**Abstract** The cornerstone of present study is to tune the electro-optical and charge transport properties of donor-bridge-acceptor (D-\(\pi\)-A) triphenylamine (TPA) derivatives. In the present investigation, an electron deficient moiety (pyrimidine), electron-rich moiety (thiophene) and oligocene (benzene, naphthalene, anthracene, tetracene and pentacene) have been incorporated as \(\pi\)-spacer between the donor TPA unit and cyanoacetic acid acceptor and anchoring group. The elongation of bridge usually affects the energy levels, i.e., higher the highest occupied molecular orbital (HOMO) while lower the lowest unoccupied molecular orbital (LUMO) thus reduces the HOMO–LUMO energy gap. The lowered LUMO energy levels of cyano-{2-[6-(4-diphenylamino-phenyl)-pyrimidin-4-yl]-tetraceno[2,3-b]thiophen-8-yl}-acetic acid (TPA-PTT4) and cyano-{2-[6-(4-diphenylamino-phenyl)-pyrimidin-4-yl]-pentaceno[2,3-b]thiophen-9-yl}-acetic acid (TPA-PPT5) dyes revealed that electron injected from dye to semiconductor surface might be auxiliary stable resulting in impediment of quenching. The broken co-planarity between the \(\pi\)-spacer conceiving...
1. Introduction

The compounds with the π-backbone showed prominent opto-electronic and charge transport properties in different high-tech fields, e.g., sensors (Niu et al., 2006), organic light emitting diodes (OLEDs) (Makoto Satsuki and Sadaharu Suga, 2007), organic field effect transistors (OFET) (Marks and Hersam, 2015) and photovoltaics (Chambon et al., 2013). Previously, numerous inorganic materials were studied with respect to the solar cell (Green et al., 2012) and to sense the humidity (Traversa et al., 1996; Li et al., 2004). The traditional technology (silicone), have environmental and economic issues. Moreover, metal oxides are being used in the film making of dye-sensitized solar cells, (DSCs) (O'Regan and Gratzel, 1991) and humidity sensors (Suri et al., 2002; Hsu et al., 2014). Nowadays, organic materials are being used due to their low cost, light weight, structural flexibility and fabrication simplicity. Finally, the organic dyes are favorite contenders for power conversion and sensing applications.

The power conversion efficiency (PCE) has been observed as 13% when using the porphyrin dye (Mathew et al., 2014) showing a competitive and potential renewable power generation technology. In DSCs, the dye sensitizer is a key component which has been widely designed and investigated to enhance the PCE that also harvests solar photons and starts charge separation from the excited state of the sensitizer into the conduction band of the semiconductor through photoinduced electron transfer (Besson et al., 2009; Han et al., 2012).

Molecular engineering to model/design efficient dyes play a vital role in tuning the electro-optical and charge transport properties, i.e., light excitation should accompany electron injection from the light-harvesting unit toward the anchoring group. This can be attained by incorporating the strong conjugation between the donor moieties and anchoring groups as well as decent electronic coupling between the lowest unoccupied molecular orbital (LUMO) of the dye and conduction band of the semiconductor. The PCE can be improved by diminishing the aggregation of the sensitizer into the semiconductor surface. Moreover, “bulk heterojunction” (BHJ) solar cells are also gaining significant attention (Hoppe and Sariciftci, 2006). The organic π-conjugated materials are being used in DSCs, BHJ solar cells and humidity sensors.

Triphenylamine (TPA) has revealed promising properties as donor (Hagberg et al., 2007; Liang and Chen, 2013) and its propeller shape can suppress the dye aggregation (Bonhôte et al., 1999). Cyanoc acid showed promising characteristics as stable anchoring and strong acceptor groups (Chen et al., 2014; Zhang et al., 2015). Usually, π-spacer can directly influence the energies of the highest occupied molecular orbital (HOMO), LUMO, absorption spectrum, and the charge separation upon photoexcitation of the sensitizer (Haid et al., 2012). Thus the choice of a suitable π-spacer is very crucial. It has been proven that thiophene would be a good constitutional unit which can increase the light harvesting efficiency and charge transport properties (Zhang et al., 2009; Tian et al., 2010). Similarly, oligocenes are also being used as proficient π-spacers to tune the electro-optical and charge transport properties (Liu et al., 2014).

Quantum chemical calculations are prevailing tools (Goedecke et al., 2012) which provide guidelines for the organized and rational tuning of the dyes (Pastore et al., 2010a,b). It is well-known that density functional theory (DFT) and Time Dependent DFT (TD-DFT) are reasonable methods to calculate electronic structures, electronic excitations, predict the electro-optical and charge transport properties of organic chromophores with adequate accurateness (Cave and Castner, 2002; Persson et al., 2006; Pastore et al., 2010b). We designed systematically five new TPA derivatives to tune the electro-optical properties and dye’s photoabsorption. In newly designed donor-bridge-acceptor derivatives TPA acts as electron donor, oligocenothiophene–pyrimidine as π-spacer and cyanac etic acid as an electron acceptor and anchoring group, i.e., cyano-[2-6-(4-diphenylamino-phenyl)-pyrimidin-4-yl]-benzo[b]thiophen-5-yl]-acetic acid (TPA-PBT1), cyano-[2-6-(4-diphenylamino-phenyl)-pyrimidin-4-yl]-naphtho[2,3-b] thiophen-6-yl]-acetic acid (TPA-PNT2), cyano-[2-6-(4-diphenylamino-phenyl)-pyrimidin-4-yl]-antra[2,3-b]thiophen-7-yl]-acetic acid (TPA-PAT3), cyano-[2-6-(4-diphenylamino-phenyl)-pyrimidin-4-yl]-tetracen[2,3-b]thiophen-8-yl]-acetic acid (TPA-PRT4) and cyano-[2-6-(4-diphenylamino-phenyl)-pyrimidin-4-yl]-pentaceno[2,3-b]thiophen-9-yl]-acetic acid (TPA-PPT5), see Fig. 1.

We have studied the energy levels and distribution patterns of the frontier molecular orbitals (HOMO, LUMO), excitation energies, oscillator strengths, electronic coupling constants, electron injection, light harvesting efficiencies and structure–properties relationship. The conclusions drawn from quantum chemical calculations are appreciated as guidelines for the synthesis of innovative proficient dyes (Casanova et al., 2010; Zhang et al., 2012).

2. Computational details

In previous studies it has been shown that DFT is good method to optimize the ground state geometries, particularly B3LYP/6-31G** level of theory is reasonable and precise choices for TPA sensitizers. Pret and co-workers optimized the ground state geometries of TPA based sensitizers at B3LYP/6-31G** level and found it to be a rational approach then they studied the charge transport properties (Pret et al., 2010). Moreover, in another study, they investigated the basis set effect on the properties of interests and did not find a significant effect on bond lengths (Pret et al., 2009). The structural and electronic
properties of TPA based dye “2-cyano-5-(4-phenyl[4-vinyl]amino)phenyl)pent-2,4-dienoic acid” (TC4) were studied at B3LYP/6-31G* level which reproduced the experimental data successfully (Xu et al., 2008). Furthermore, TDDFT (Sun et al., 2007; Zhang et al., 2008) TD-CAM-B3LYP/6-31G* level has been adopted to shed light on the light harvesting efficiencies (LHE), absorption spectra, oscillator strengths and excitation energies of TPA based sensitizers. Thus in the present study, the ground state geometries were optimized at B3LYP/6-31G* level of TPA theory then excitation energies and oscillator strengths were computed by adopting the TD-CAM-B3LYP/6-31G* level of theory. All calculations were performed by G09 software (Frisch et al., 2009).

Generally Marcus theory (Eq. (1)) is used to shed light on the charge transfer rate (Marcus, 1993; Matthews et al., 1996; Hilgendorff and Sundström, 1998; Pourtois et al., 2002; Hsu, 2009). The charge injection driving force (Eq. (1)) can be calculated by

\[ \Delta G_{\text{inject}} = E_{\text{OX}}^\text{dyne} - E_{\text{CB}}^\text{TiO2} \]  

(4)

The free energy change (in electron volts, eV) for the electron injection could be given as (Katoth et al., 2004).

\[ \Delta G_{\text{inject}} = E_{\text{OX}}^\text{dyne} - E_{\text{CB}}^\text{TiO2} \]  

(4)

Here the oxidation potential of the dye at the excited state is \( E_{\text{OX}}^\text{dyne} \) and the reduction potential of the semiconductor’s conduction band is given by \( E_{\text{CB}}^\text{TiO2} \) (Hagfeldt and Graetzel, 1995; Asbury et al., 2001; Katoth et al., 2004)). The \( E_{\text{OX}}^\text{dyne} \) can be extracted from the redox potential of the ground state \( E_{\text{OX}}^\text{dyne} \) and the vertical transition energy corresponding to the photo-induced ICT,

\[ E_{\text{OX}}^\text{dyne} = E_{\text{OX}}^\text{dyne} - \lambda_{\text{ICT}} \]  

(5)

where \( \lambda_{\text{ICT}} \) is the ICT energy. It is noteworthy that this equation is only effective if the entropy variation during the light absorption procedure could be ignored.

The \( \Delta G_{\text{inject}} \) and \( E_{\text{OX}}^\text{dyne} \) have been evaluated using Eqs. (4) and (5).

The LHE can be evaluated as (Nalwa, 2001):

LHE = 1 - 10^{-A} = 1 - 10^{-f}  

(6)

where \( A \) and \( f \) are the absorption and oscillator strengths of the dye related to the \( \lambda_{\text{max}} \) respectively. Details can be found in references (Preat, 2010; Preat et al., 2010).

The efficiency (\( \eta \)) of solar cells can be determined by using the following equation

\[ \eta = FF \frac{V_{oc}J_{sc}}{P_{inc}} \]  

(7)

where \( J_{sc} \) is the short-circuit current density, \( V_{oc} \) is the open-circuit photovoltage, \( FF \) is the fill factor, and \( P_{inc} \) is the intensity of the incident light. The \( J_{sc} \) can be evaluated as

\[ J_{sc} = \int \text{LHE}(\lambda)\phi_{\text{incident}}d\lambda \]  

(8)
where \( \eta_{\text{collection}} \) is the charge collection efficiency which is constant. From the above equation, it can be found that \( J_{\text{sc}} \) is directly linked with the LHE and \( \phi_{\text{injection}} \) that is electron injection efficiency which is related to \( \Delta G_{\text{inject}} \). It is revealed that higher LHE and \( \Delta G_{\text{inject}} \) would lead to result in efficient devices (Zhang et al., 2013).

3. Result and discussion

3.1. Electro-optical properties

In Fig. 2, we have illustrated the charge density distribution patterns of the ground state highest occupied molecular orbitals and lowest unoccupied molecular orbitals which contribute in the transitions, e.g., HOMOs (H), HOMOs−1 (H−1), HOMOs−2 (H−2), LUMOs (L), LUMOs+1 (L+1) and LUMOs+2 (L+2) of five TPA based sensitizers. In TPA-PBT1, a major transition has been observed \( H \rightarrow L \) in which HOMO is delocalized on the TPA moiety whereas LUMO is localized on the benzothiophene and pyrimidine units. The absorption wavelength (\( \lambda_a \)) for this transition has been observed as 337 nm with the oscillator strength (\( f \)) 1.0374. In TPA-PNT2, two significant transitions have been noticed \( H_{-1} \rightarrow L \) and \( H_{-1} \rightarrow L+1 \) with the \( f \) 0.6871 and 0.7902 showing at the \( \lambda_a \) 349 and 274 nm wavelengths. In this sensitizer, the charge density in HOMO−1, HOMO, and LUMO is distributed on napthothiophene, TPA and napthothiophene pyrimidine cores, respectively while in LUMO+1, most of the charge is distributed on pyrimidine and phenyl rings of the TPA while some charge is localized.

![Figure 2](image_url)  
**Figure 2** The charge density distribution of the frontier molecular orbitals (0.035 contour value) of triphenylamine based dye at the B3LYP/6-31G** level of theory.
on the naphthothiophene moiety. In TPA-PAT3, two significant transitions have been observed H → L and H → L−1 → L with the f 0.1465 and 1.2423 showing the λε 413 and 341 nm. In this dye, the charge density in HOMO−1 and HOMO is distributed on the entire dye while in LUMO on anthrathioaphene units. In TPA-PPT4, two significant transitions have been observed H → L and H−2 → L with the f 0.0866 and 1.2674 showing at the λε 499 and 354 nm wavelengths. In this dye, the charge density in HOMO is distributed on tetracnaphthiophene while HOMO−2 and LUMO on tetracnaphthiophene and pyrimidine. In TPA-PPT5, two significant transitions have been observed H → L and H−4 → L + 4 with the f 0.0698 and 1.7681 showing at the λε 599 and 297 nm wavelengths. In this dye, the charge density in HOMO is distributed on penta-ncnaphthiophene, LUMO on pentacnaphthiophene and pyrimidine and LUMO+4 on pentace and acceptor moiety.

In Table 1, we have tabulated the computed HOMO energies (E\text{HOMO}). LUMO energies (E\text{LUMO}) and energy gap (E\text{g}) of five TPA-based sensitizers at B3LYP/6-31G** level of theory. The trend of the HOMO energies (E\text{HOMO}) is TPA-PNT2 > TPA-PAT3 > TPA-PAT1 > TPA-PN T2, whereas, LUMO energies (E\text{LUMO}) is TPA-PBT1 > TPA-PNT2 > TPA-PAT3 > TPA-PPT4 > TPA-PPT5 while HOMO−LUMO energy gaps (E\text{g}) is TPA-PBT1 > TPA-PNT2 > TPA-PAT3 > TPA-PPT4 > TPA-PPT5. We have observed that by elongating the bridge Et usually decreases. The smaller E\text{g} of TPA-PNT2, TPA-PAT3, TPA-PPT4 and TPA-PPT5 than TPA-PBT1 show that DSCs performance of these sensitizers would be greater than the later one. Considerably lowered LUMO energy levels would not only enhance the electron injection ability but also make such sensitizers unsusceptible to oxidation. The smaller E\text{g} of TPA-PNT2, TPA-PAT3, TPA-PPT4 and TPA-PPT5 sensitizers also showed that injected electrons might be supplementary stable, which would result in hindering the quenching. Moreover, the trend of the E\text{g} is in good agreement with λε. A significant red shift has been observed by increasing the conjugation/bridge elongation, i.e., 12, 76, 162 and 262 nm form TPA-PNT2, TPA-PAT3, TPA-PPT4 and TPA-PPT5 compared to the TPA-PBT1 revealing efficient visible light sensing/absorbing sensitizers. Moreover, it is also expected that these dyes can be used as sensors having the sensing aptitudes of metal ions in the UV–Visible wavelengths.

### 3.2. Electron injection

The ΔG\text{inject} (ΔG\text{inject}^\text{TPA/dye}) and ΔG\text{inject} (ΔG\text{inject}^\text{TPA/dye}) of newly designed derivatives reveal that these materials might be proficient sensitizers.

The comprehensive intra-molecular charge transfer has been observed from the donor to the acceptor side. The bridge elongation is favorable to enhance the ΔG\text{inject} and |V\text{RP}|. The LHE of TPA-PBT1 has been observed as 0.908. By introducing the naphthalene ring as in TPA-PNT2 decreases the LHE to 0.794 and 0.838 for two major excitations. In TPA-PAT3, the LHE has been observed to be 0.286 and 0.943; in TPA-PPT4, 0.180 and 0.946; in TPA-PPT5, 0.148 and 0.983 for two major excitations, respectively. Thus it has been concluded that bridge elongation enhances the LHE and is nicely comparable with the earlier study.

All the studied sensitizers have acidic moieties which are good light harvesting sites as well as being helpful to anchor with the TiO\text{2} surface. These acidic units would also enhance

### Table 1

The electron injection (ΔG\text{inject}), relative electron injection (ΔG\text{inject}^\text{TPA/dye}) oxidation potentials, light harvesting efficiencies (LHE), electron coupling constants (|V\text{RP}|), absorption (λε) in nm, oscillator strengths (f) and transitions of TC4 and studied TPA dyes.

| Systems | ΔG\text{inject} | E\text{red} | E\text{ox} | ΔE\text{g} | λε | f | LHE | ΔG\text{inject}^\text{TPA/dye} | |V\text{RP}| | λε | Transition |
|---------|----------------|------------|------------|-------------|------|---|-----|------------------|-----|------|---------|

| TPA-PPT5| −1.46          | 4.61       | 2.54       | 2.07        | 0.0698 | 0.148 | 0.85 | 0.730           | 599 | H → L   |
|         | −3.56          | 4.61       | 0.44       | 4.17        | 1.7681 | 0.983 | 2.08 | 1.780           | 297 | H−1 → L |

ΔG\text{inject} = relative electron injection ΔG\text{inject}^\text{TPA/dye}/ΔG\text{inject} (TC4).

All the parameters were calculated at B3LYP/6-31G** and TD-CAM-B3LYP/6-31G** levels of theories for TC4 (2-cyano-5-(4-(phenyl(4-vinylphenyl)amino)phenyl)pent-2,4-dienoic acid) (Irфан, 2013) and TPA derivatives.
the solubility in solution and reduce the aggregation (Robertson, 2006). It is expected that these sensitzers would be more stable after anchoring on the TiO₂ surface. Moreover, acidic ligands would be promising positions to transfer the electrons from dyes to the TiO₂ surface. Additionally, it has been studied that the dye which shows high affinity for H₂O molecules would lead to the proficient humidity sensor (Azmer et al., 2015). In our studied TPA dyes, the carboxylic group would be the favorable site and shows high affinity for H₂O molecules. It is expected that –COOH would be promising position for the humidity sensing.

3.3. Electronic properties

The HOMO and LUMO energies of Si are −5.43 and −3.92 eV (Liu et al., 2008) while TiO₂ are −7.40 and −4.20 eV, respectively (Kuo et al., 2008). The successful operation of a photo-voltaic device requires a staggered band alignment heterojunction which allocate electrons to transport to the cathode and holes to the anode. By considering the average values both for Si and TiO₂, the valence band energy has been found to be −6.41 eV while the conduction band energy is −4.06 eV (Si/TiO₂). It is expected that Si/TiO₂ as the acceptor would behave as a staggered band alignment heterojunction, see Fig. 3. In hybrid solar cells, excitons formed in the donor material are dissociated at the D–A interface. The force essential to overcome the exciton binding energy is provided by the energy level offset of the LUMO of the donor and the conduction band edge of the acceptor material (Wright and Uddin, 2012). We found energy level offset 1.50, 1.99, 1.85, 1.66, 1.46, and 1.28 eV for TC4, TPA-PBT1, TPA-PNT2, TPA-PAT3, TPA-PTT4 and TPA-PPT5, respectively to overcome the exciton binding energy. For dissociation of excitons formed in the acceptor material, the energy offset of the HOMO of the donor and the valence band edge of the acceptor material is required. We found energy level offset to be 1.11, 1.21, 1.20, 1.23, 1.49, 1.72 eV for TC4, TPA-PBT1, TPA-PNT2, TPA-PAT3, TPA-PTT4 and TPA-PPT5, respectively. Scharber and coworkers concluded that \( V_{oc} \) is directly proportional to the diagonal band gap of the heterojunction (Scharber et al., 2006), whereas in another study by Yamanari it has been found that there is no linear relationship between the diagonal band gap and \( V_{oc} \) (Yamanari et al., 2009). In the present study, the diagonal band gaps for TC4, TPA-PBT1, TPA-PNT2, TPA-PAT3, TPA-PTT4 and TPA-PPT5 have been observed 1.24, 1.14, 1.15, 1.12, 0.86, 0.63 eV, respectively. Thus from these values, we are unable to conclude that either \( V_{oc} \) would enhance or reduce the efficiency. But it is understood that \( V_{oc} \) is not only the factor which can improve the efficiency. In our previous study, we found the measured \( V_{oc} \) 0.53 and 0.60 V for 2-[4-[2-(4-hydroxy benzylidene)hydrazinophenyl]ethylenel-1,1,2-tricarbonitrile (dye2) and hydrazone 2-[4-[2-(4-hydroxybenzylidene)hydrazinophenyl]ethylenel-1,1,2-tricarbonitrile (dye1) with efficiencies of 3.58% and 2.76%, respectively. The superior efficiency in hydrazone dye2 was observed due to the larger \( J_{sc} \) and FF values (Al-Schemi et al., 2014). On the other hand, it is expected that higher LHE and \( \Delta G_{inject} \) would lead to result in efficient devices due to the improved \( J_{sc} \).

4. Conclusions

Our results exhibited that by elongating the bridge HOMO–LUMO energy gap decreases in triphenylamine derivatives. The smaller energy gaps of TPA-PNT2, TPA-PAT3, TPA-PTT4 and TPA-PPT5 than TPA-PBT1 show that performance of former dyes would be greater than the later one. Considerably lowered LUMO energy level would not only enhance the electron injection ability but also make such dyes unsusceptible to oxidation. The smaller LUMO energies of TPA-PNT2, TPA-PAT3, TPA-PTT4 and TPA-PPT5 sensitizers also showed that injected electrons might be supplementary stable, which would impede the quenching. Bridge elongation improves the electron injection, electron coupling constants and light harvesting efficiencies. The Si/TiO₂ as acceptor materials might be favorable for staggered band alignment that would be best for charge transport from donor to acceptor moieties. The co-planarity between the bridge having LUMO and the TPA moiety is broken ensuing a positive charge that may not directly fall to the TiO₂ surface, subsequently obstructing the recombination process. The electron injection of 2-cyano-5-(phenyl(4-vinylphenyl)amino)phenylpenta-2,4-dienoic acid (TC4) was observed to be −1.71. The electron injection of TPA-PBT1, TPA-PNT2, TPA-PAT3, TPA-PTT4 and TPA-PPT5 is 1.50, 1.98, 1.34, 1.54 and 2.08 times superior to TC4. Moreover, the superior electron injection, relative electron injection and electron coupling constants of new designed photosensitizers revealed that these dyes might be proficient as compared to the TC4. It is also expected that higher light harvesting efficiencies and electron injection would improve the short-circuit current density which lead to proficient multifunctional devices.
